Intestinal Motility Experiment

Dr. Tamara Alqudah

Aim of the experiment

- This experiment investigates the contraction of smooth muscle in the small intestine by :

1. Observing the occurrence of rhythmical contractions
2. The modification of these contractions by acetylcholine and atropine.

Method

- In our experiment we use the small intestine (SI) of the rat.
- Small pieces (2-3cm) of the SI are hanged vertically by a thread to a glass hook in an organ bath.
- The organ bath contains warm ($37^{o}C$) oxygenated buffer. This is essential to maintain the viability of the tissue.
- The SI is connected by a thread to a tension transducer
- The tension transducer converts the mechanical signal generated by the contraction of the small intestine to an electric signal and conveys it to a special software
- The software is capable of displaying a simple graph of tension versus time.

- After hanging the tissue it is allowed to rest for 15-20 minutes to allow the muscle to recover normal function after being handled.
- The tension created by the small intestinal segment is recorded.
- Then Acetylcholine is added to the organ bath.
- Finally Atropine is added to the organ bath.

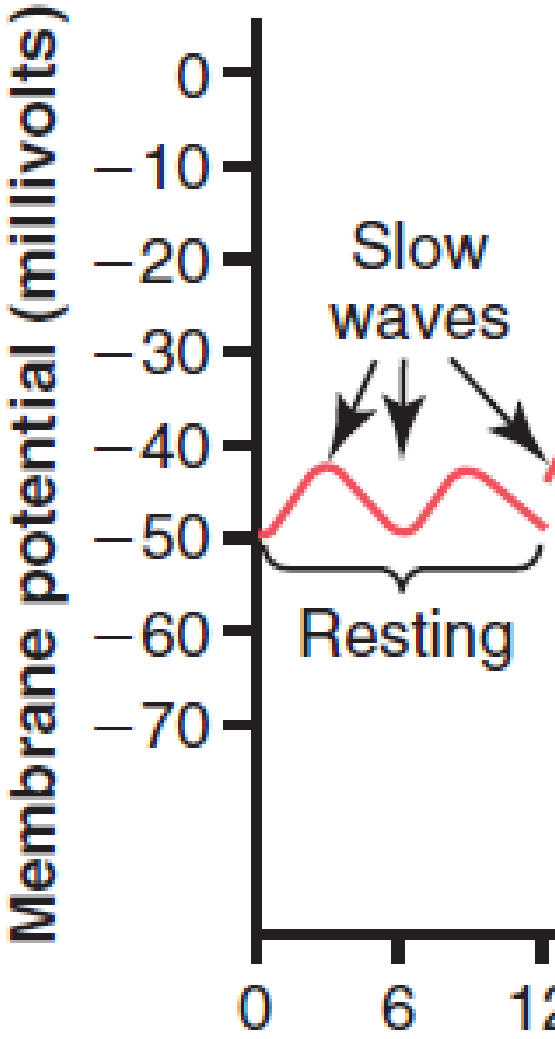
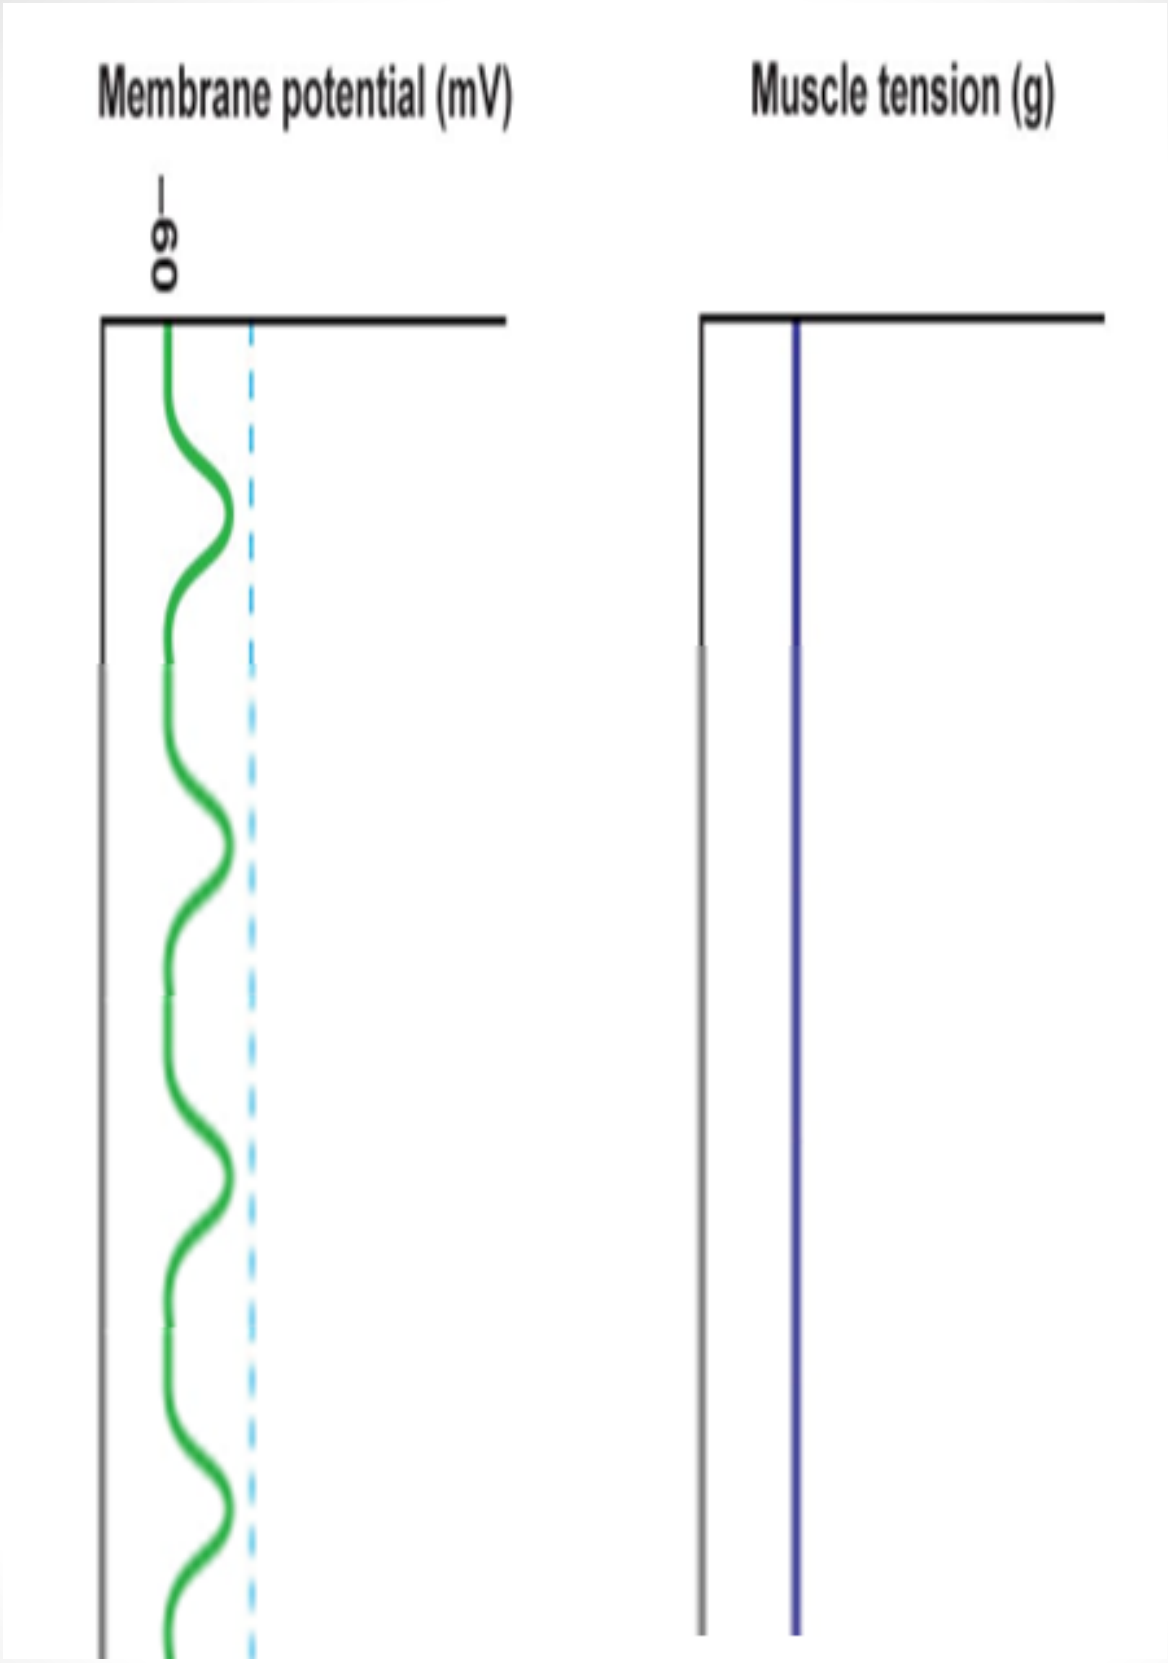
Discussion

- Most gastrointestinal contractions occur rhythmically.
- Phasic (Rhythmical)contractions: periodic contractions and relaxations.
- Smooth muscle in the small intestine contracts rhythmically in the absence of neuronal or hormonal stimulation.
- The rhythm is determined mainly by the frequency of the “slow waves” .
- The slow waves are generated by the interstitial cells of Cajal (ICC), which are believed to act as electrical pacemakers for smooth muscle cells.

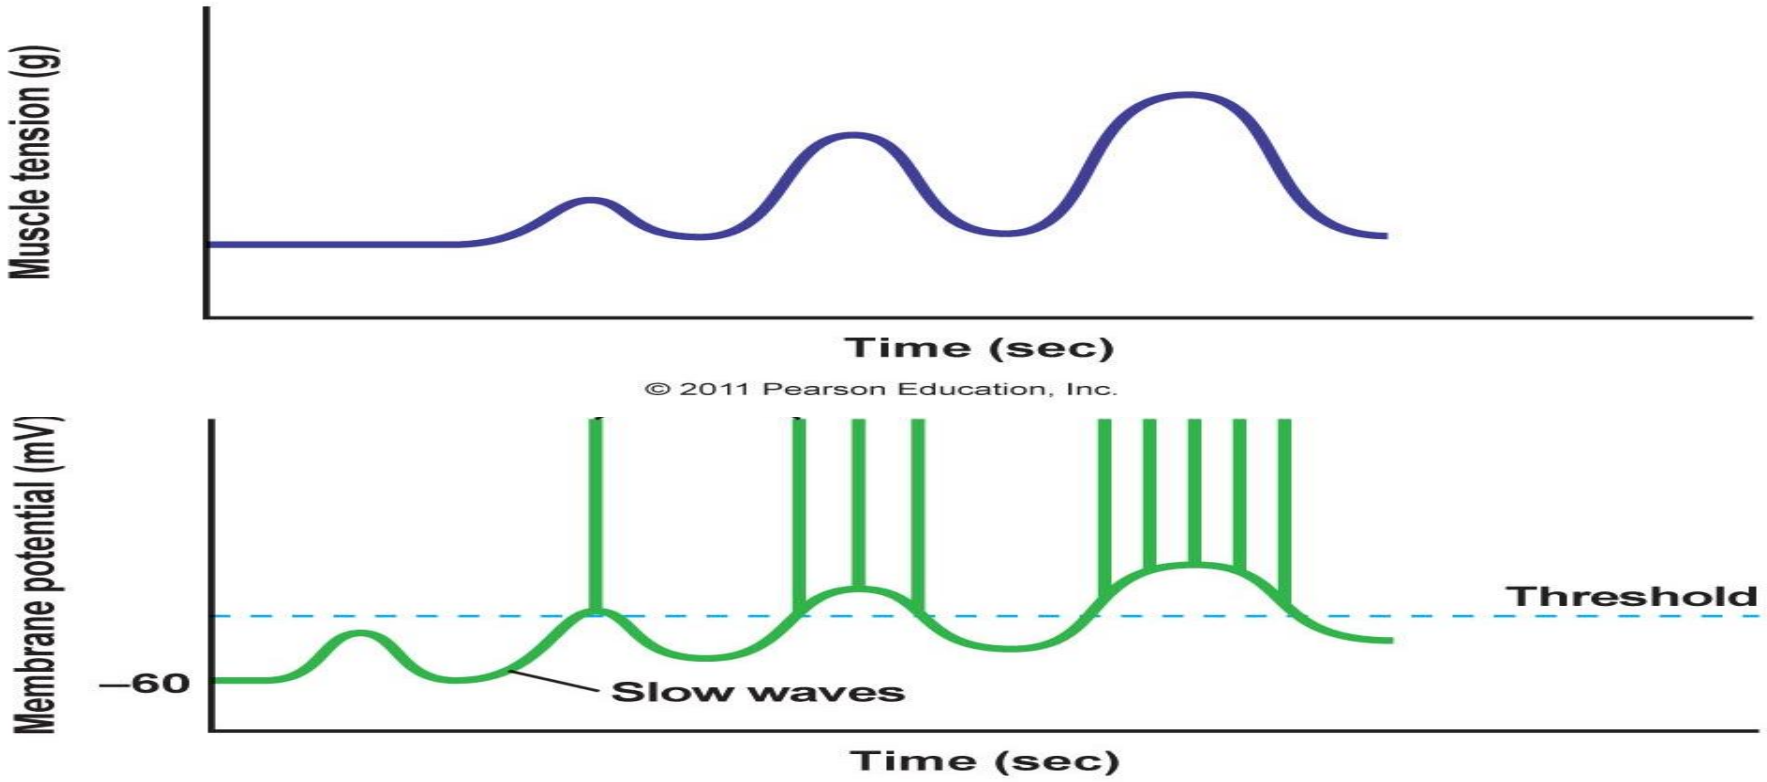
- Slow waves are slow, undulating changes in the resting membrane potential.
- Slow waves occur at different frequencies at various points along the gastrointestinal tract. In humans their frequency is 12/minute in the duodenum, 8-9/minute in the ileum.
- Slow waves set the maximum frequency at which contraction can occur at a particular site.



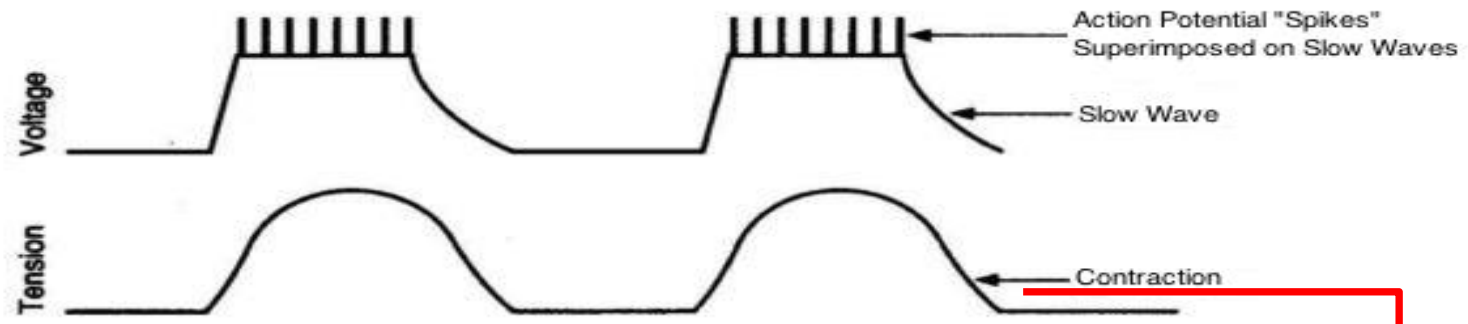


Membrane potential (mV)
-60
Muscle tension (g)

- For a contraction to occur, a spike potential must be generated by smooth muscle cells, seen as transient membrane depolarization superimposed on the peak of the slow wave.
  - They are true action potentials
  - Stimulated by stretch, acetylcholine and some GI hormones



- Remember that in our experiment we measured the actual contraction of the small intestine NOT the slow waves .



This is what we measured

- Ach is the major excitatory neurotransmitter in the small intestine
- Secreted by enteric neurons and parasympathetic neurons
- Acetylcholine promotes increased contractile force
  - The increase in contractile force is due to an increase in the number spikes not in the frequency of slow waves.

- Its effect on intestinal smooth muscle cells is mediated through muscarinic receptors
  - Inhibition of the contractile effect of ACh is mediated by adding atropine; a competitive antagonist of Ach at the muscarinic receptor.
